ABSTRACT

The impact of trades on price dynamics in the European sovereign debt markets is of significant importance to policy makers and market participants. This paper uses high-frequency quote and transaction data from the MTS European sovereign bond inter-dealer platform to investigate price-order-flow dynamics from July 2005 until December 2011 for Germany, France, Portugal, Italy, Ireland, Spain and Greece. We find that order-flow had a larger impact on quote revision in a relatively low-intensity trading environment than in a relatively high-intensity trading environment implying that informed traders should only execute in low-intensity trading environments when they value immediacy over discretion. This analysis is consistent with the limited prior literature for European debt markets. Our analysis indicates that this relationship persists during turbulent market conditions. Also, we find that the impact of order-flow on subsequent trades was larger during periods of high-trading intensity implying that market participants use order splitting trading strategies.

ABSTRACT

The impact of trades on price dynamics in the European sovereign debt markets is of significant importance to policy makers and market participants. This paper uses high-frequency quote and transaction data from the MTS European sovereign bond inter-dealer platform to investigate price-order-flow dynamics from July 2005 until December 2011 for Germany, France, Portugal, Italy, Ireland, Spain and Greece. We find that order-flow had a larger impact on quote revision in a relatively low-intensity trading environment than in a relatively high-intensity trading environment implying that informed traders should only execute in low-intensity trading environments when they value immediacy over discretion. This analysis is consistent with the limited prior literature for European debt markets. Our analysis indicates that this relationship persists during turbulent market conditions. Also, we find that the impact of order-flow on subsequent trades was larger during periods of high-trading intensity implying that market participants use order splitting trading strategies.

1. Introduction

This paper contributes to the literature examining price-order-flow dynamics on European sovereign bond markets. It analyses Mercato dei Titoli di Stato (MTS) high frequency data for French, German, Greek, Irish, Italian, Portuguese and Spanish government bonds from 1 July 2005 to 31 December 2011 that captures the impact of the global financial crisis and European sovereign debt crisis. The specific aim of the paper is to provide a comprehensive analysis of European sovereign bonds market through a period of crisis to evaluate the price-order-flow relationship, conditional upon periods of varying levels of trading intensity.

Executing an order is expensive. By aggressing a quote or limit-order the price taker must pay the bid-ask spread for immediacy, as well as risk exposing valuable information and moving the price in the direction of their trading. In a market like MTS, where the liquidity and transactions costs are visible to market participants, other low-visible measures of market quality and liquidity are important. For example, market impact, price trend, and timing risk. Cheung *et al.* (2005) also analyse MTS high-frequency data from January 2001 until May 2002 that allowed them to examine how trades are absorbed during periods of high- and low-intensity trading. Predictions from the literature on the impact of trades conditional upon trading intensity is ambiguous. A number of papers argue that informed market participants want to trade as much as possible without being detected. Consequently, they trade during high-intensity trading periods when liquidity traders are active. This logic implies that an unexpected trade during a high intensity trading period would have a larger impact on price (Kyle, 1985; Easley and O'Hara, 1992). Conversely, short-selling constraints may lead to a decrease in the probability of a market maker facing an informed trader with bad news, implying that an unexpected trade during a low intensity trading period would instead have a larger impact on price (Diamond and Verrechia, 1987).

To answer this question empirically, an analysis of the price process is needed which requires the simultaneous modelling of price and order-flow dynamics, taking trading intensity into account. Dufour and Engle (2000) introduce an approach for testing and assessing the role played by the waiting time between consecutive transactions in the process of price formation. For US stock market data they find that trades had most impact on prices in busy markets. Cohen and Shin (2003) conduct a comparable analysis for the US Treasury market. By dividing their dataset into days with and without news announcements, they find that the effect of trades

on returns was higher on announcement days. However, they do not explicitly include intraday trading intensity in their analysis. In contrast when intra-daily data is incorporated into the analysis, Cheung *et al.* (2005) report that the impact of a trade in a relatively low-trading intensive environment had a larger impact on price than in a relatively high-trading intensive environment.

Three distinct periods over our sample period are classified as calm, global financial crisis and European sovereign debt crisis to examine how the effect of trades on prices using a modified version of the methodology proposed by Dufour and Engle (2000). We evaluate the interaction between returns and order-flow and assess whether trades were better absorbed by market makers in periods of high- or low-trading intensity. We find that for the majority of countries in the majority of periods there was an instantaneous upward (downward) price movement following a buy (sell) trade, and that order-flow had a larger impact on quote revision during relatively low-intensity trading periods than in the relatively high intensity trading periods. This finding supports the short-selling constraints theory posited by Diamond and Verrechia (1987) and implies that price impact on the MTS market can be minimised by splitting large orders into multiple smaller orders and dripping them into the market over a longer period, ideally during busier trading conditions. Further, we find that order-flows were strongly correlated, and the impact of order-flow on subsequent trades was larger during periods of high-trading intensity. This implies that market participants use order splitting as part of their trading strategy, and that there are multiple informed traders acting on the same private information.

The rest of the paper is organized as follows: Section 2 provides a detailed explanation of the data and how it was constructed, Section 3 outlines the methodology employed to model two dynamic equations for price changes and signed quantities, Section 4 reports the empirical results, while Section 5 summarizes the key findings from our analysis and suggests an important area for further research given recent regulatory changes.

2. European sovereign bond market data

The MTS data covers every transaction for French, German, Greek, Irish, Italian, Portuguese and Spanish government bonds being traded on the MTS platform from 1 July 2005 to 31 December 2011. For each instrument included in the study the limit-order book is available in aggregate format with millisecond timestamp. Specifically, the total aggregated volumes of the top three price levels of the limit-order book as well as any changes such as new quotes and orders, updates, and cancellations. Similarly, trades are recorded with a timestamp accurate to one millisecond, and the direction of the trade (buy or sell) is recorded.

For the benchmark liquidity analysis, to give an accurate picture of the market and to avoid yield curve effects, we conduct the analysis on the current benchmark instrument for three different durations: short, medium, and long. As per Dunne et al. (2007), and in accordance with industry standard, the short-, medium- and long-term maturity buckets are defined as 1 to 3.5 years, 3.5 to 6.5 years and 6.5 to 13.5 years respectively. When selecting instruments for the benchmark analysis we select the most recently issued instrument within each maturity bucket. The larger economies of France, Germany and Italy have a regular issuance of debt at all maturities. Accordingly, we roll the benchmark instruments on the day of issuance or the first date where the instrument is available for trading on the MTS platform. The smaller economies of Greece, Ireland, Portugal and Spain issue debt less frequently. Especially during the crisis periods. As such, in some instances the situation arises where it is not possible to simply roll to a newly issued benchmark.

INSERT TABLE 1 ABOUT HERE

Formally, to select the benchmark bond for a given maturity bucket, we use the following criteria: For each maturity bucket, starting at 1 July 2005, select the most recently issued instrument with maturity fitting into said maturity bucket. This instrument is the benchmark instrument until either a) a new instrument is issued that fits into the maturity bucket, or b) the current instrument leaves the maturity bucket. In the case of b), we assume that there has not been a new instrument issued that fits into the maturity bucket, in which case we select the most recently issued instrument in the maturity bucket. If none exists, we wait until a) a new bond is issued that fits into the maturity bucket, or b) an existing bond moves into the maturity bucket. It happens for Ireland during the sample period that there is one instance for each short and medium benchmark where no bond fits the maturity bucket. It is not possible to calculate

metrics during these periods. It is not always possible to find benchmark instruments being quoted on both EuroMTS and MTS Domestic Markets for the short and medium maturities. Consequently, the analysis on the long maturity benchmarks is conducted on the aggregate order book across both market segments, and the analysis on the short and medium maturities is limited to the MTS Domestic Markets segment only. Table 1 provides an overview of the benchmark bonds in the dataset for short, medium and long duration for each country.

Since several significant events took place during our study period, in addition, we divided the full sample into four sub-periods:

- Calm Period (PRE): 1st July 2005 to 14th July 2007.
- Global Financial Crisis (GFC): 15th July 2007 to 15th January 2009: From July 2007, banks in the UK stopped lending to each other due to market fears that counterparts were exposed to the emerging US sub-prime crisis. In July, Bear Sterns informed investors that they would get little, if any, money back from two hedge funds with large holdings of sub-prime mortgages. LIBOR rates spike. Following a BBC report on the 13th September, Northern Rock experienced a bank-run on the 14th. It was subsequently nationalised on 22nd February 2008.
- European Sovereign Debt Crisis: 16th January 2009 to 7th May 2010: On 15th January 2009, the Irish government announced that it would nationalise Anglo Irish Bank. Fall 2009 Greece's budget was revised highlighting that the deficit for that year would be significantly higher than previously predicted. On 2nd May 2010 the EU endorsed the IMF announce an €85bn first European financial rescue plan for Greece. From 8th May 2010 to 31st December 2011, problems persisted and Greece and a second rescue package was negotiated with Greece in 2011. On 28th November 2010 the Troika (European Commission, European Central Bank and International Monetary Fund) agreed an €85bn bailout deal with the Irish Government. On 5th May 2011, Portugal agrees with the EU and IMF on a €78bn bailout in exchange for an austerity programme. Pelizzon et al. (2016) show that for Italian sovereign bonds it was not until the start of 2012 that ECB interventions (the Long-Term Refinancing Operations: LTRO) diminished the impact of credit risk which suggests it wasn't until this point that the crisis period ended economically. Splitting the European sovereign debt crisis period into two periods allows us to evaluate each period individually and against each other.

3. Methodology

Price impact is modelled by taking order-flow dynamics and trading intensity into account using the VAR model proposed by Dufour and Engle (2000). The model is a system of two dynamic equations. One for price changes (returns) and one for signed quantities with lagged values of both variables as explanatory variables. This model facilitates the analysis of the interaction between order-flow and returns in the form of impulse responses of a shock (an unexpected trade) to the trading process. The main advantage of this model is the dynamic setup between order-flow and price return that is important because participants on the MTS trading platforms can continuously view live quotes and are able to extract information from the live quote updates. Therefore, the process of market making not only depends on the concurrent price and trade but also on the previous changes in price and order-flow. Lagged traded quantity is also important as the MTS trading system allows the splitting of orders and it is likely that the observed order book is the drip quantity instead of the total (block) quantity.

Following Dufour and Engle (2000), we make the coefficients a function of trading intensity defined as the reciprocal of the number of minutes between two trades with coefficients also depending on the location of the trade, i.e. whether the trade occurred on EuroMTS or the MTS Domestic Markets. The subscript t denotes sequential transaction time, either trade or quote update. The model is as follows:

$$r_t = \bar{\alpha}^r + \sum_{i=1}^P (\bar{\beta}_i^r + \bar{z}_i^r \ln(T_{t-i})) r_{t-i} + \sum_{i=0}^P (\bar{\gamma}_i^r + \bar{\delta}_i^r D_{t-i} + \bar{\tau}_i^r \ln(T_{t-i})) Q_{t-i} + \varepsilon_{1,t} \quad (1)$$

$$Q_t = \bar{\alpha}^Q + \sum_{i=1}^P (\bar{\beta}_i^Q + \bar{z}_i^Q \ln(T_{t-i})) r_{t-i} + \sum_{i=1}^P (\bar{\gamma}_i^Q + \bar{\delta}_i^Q D_{t-i} + \bar{\tau}_i^Q \ln(T_{t-i})) Q_{t-i} + \varepsilon_{2,t} \quad (2)$$

where $r_t = 10,000 \ln(P_t/P_{t-1})$ is the change in the logarithm of mid-quote prices, Q_t is the signed trade quantity in millions, T_t is the time in minutes between a trade and the previous trade (0 for quotes), D_t is market dummy variable equal to 1 if the trade was on EuroMTS and 0 if it was on the MTS Domestic Markets. Equation 1 primarily analyses the effect of trades on quote revision, while also accounting for lagged returns. The key parameters for discussion are $\bar{\gamma}_i^r$, $\bar{\delta}_i^r$ and $\bar{\tau}_i^r$. Given the dependent variable is $r_t = 10,000 \ln(P_t/P_{t-1})$ the implications of the results of the returns regressions are as follows:

- The expected instantaneous price reaction of a one million buy trade on MTS Domestic Markets is γ_0^r basis points.
- The expected instantaneous price reaction of a one million buy trade on EuroMTS is $\gamma_0^r + \delta_0^r$ basis points.

- The expected instantaneous price reaction of a one million buy trade on MTS Domestic Markets given a duration $\ln(\tau^*)$ is given by $\gamma_0^r + \tau_0^r \ln(\tau^*)$.
- The expected instantaneous price reaction of a one million buy trade on EuroMTS given a duration $\ln(\tau^*)$ is given by $\gamma_0^r + \delta_0^r + \tau_0^r \ln(\tau^*)$.

In the returns equation:

- The γ_i^r parameters reflect the interaction between signed trade quantity and return
- The δ_i^r parameters account for market sector in the interaction between signed trade quantity and return.
- The τ_i^r parameters account for trading intensity in the interaction between signed trade quantity and return.

For the quantity equation:

- The γ_i^Q parameters account for lagged signed trade quantity.
- The δ_i^Q parameters account for market sector.
- The τ_i^Q parameters account for trading intensity.

4. Empirical results

4.1. Impact of trading on prices

Table 2 reports the results for the returns model equation 1. The γ_i^r parameters, reported in panel B, reflect the interaction between signed trade quantity and return. Looking first at the core countries in the calm period, the γ_0^r parameter is positive for the German benchmark. A positive coefficient indicates that there was an instantaneous upward (downward) price movement following a buy (sell) trade, which is consistent with Cheung et al. (2005). Adversely, the parameter is negative and statistically significant

for France. A negative coefficient indicates that there was an instantaneous downward (upward) price movement following a buy (sell) trade, and so this finding is unexpected. For the remaining two periods, global financial crisis and European sovereign debt crisis, γ_0^r is positive for both countries. For the semi-core countries during the calm period, the γ_0^r parameter is negative for Italy but positive for Spain. During the global financial crisis, it is positive for Italy but negative for Spain. During the European sovereign debt crisis, it is positive for both Italy and Spain. The peripheral countries show similar findings, with the γ_0^r parameter positive for all three countries in the calm period. During the global financial crisis it is negative for Portugal. During the European sovereign debt crisis, it is positive for Ireland, with Portugal and Greece being negative. Lagged values are strongly positive across all countries. This is consistent with the findings of Cheung et al. (2005), and can be attributed to active position building.

INSERT TABLE 2 ABOUT HERE

As above, the expected instantaneous price reaction of a one million buy trade on the domestic platform is γ_0^r basis points. Additionally, the values for the expected instantaneous price reaction of a five million buy trade on MTS Domestic Markets and EuroMTS have been calculated and are reflected in Table 4. Of the 21 variables reflecting the price reaction on MTS Domestic Markets, there are 15 positive values and 6 negative values indicating that on MTS Domestic Markets for the majority of countries in the majority of periods there was an instantaneous upward (downward) price movement following a buy (sell) trade. The δ_1^r parameters account for market sector in the interaction between signed trade quantity and return. Recall that the dummy variable D_{t-1} is set equal to 1 for trades on EuroMTS, and 0 for trades on MTS Domestic Markets. In the calm period, δ_0^r is positive for Germany, France, Italy and Spain, implying that a trade on the EuroMTS had a larger instantaneous impact on price relative to the same trade on MTS Domestic Markets. However, it is negative for the three peripheral countries of Greece, Ireland and Portugal in the same period implying that a trade on EuroMTS had a lower instantaneous impact on price relative to the same trade on MTS Domestic Markets. During the European sovereign debt crisis, δ_0^r is positive for all countries and statistically significant for France, Greece, Portugal and Spain, implying that a trade on EuroMTS had a higher instantaneous impact on price relative to the same trade on MTS Domestic Markets. This result should be viewed in context with Figure 1, which shows that there was a marked decrease in the number of trades on EuroMTS compared to MTS Domestic Markets during the European sovereign debt crisis.

INSERT FIGURE 1 ABOUT HERE

The values for the expected instantaneous price reactions of a five million trade on the EuroMTS and MTS Domestic platform are reported in Table 4. Of the 21 variables, there are 16 positive values and 5

negative values indicating that on the EuroMTS platform for the majority of countries in the majority of periods there was an instantaneous upward (downward) price movement following a buy (sell) trade. The τ_i^r parameters account for trading intensity in the interaction between signed trade quantity and return. The τ_0^r parameter is positive for all countries and periods except for Italy during the global financial crisis. This implies that the larger the quantity being traded the larger the instantaneous price reaction, and that the reaction was strongest when trading intensity was low. Knowledge of the impact that trade execution has on price is particularly relevant for informed traders who are trying to minimise the price impact of trading, as they may want to minimise price impact in order to conceal privileged information. This result implies that price impact on the MTS market can be minimised by splitting large orders into multiple smaller orders and dripping them into the market over a longer period. This strategy would however expose market participants to the risk of an adverse price movement. They may prefer to execute the whole volume in one order at the best price regardless of the resulting price impact. This result is consistent with Cheung et al. (2005) who also find that the impact of a trade in a relatively low intensity trading environment had a larger impact on price for the MTS market in 2001-02. However, it differs to the finding of Dufour and Engle (2000) in their analysis of stock markets.

4.2. Quantity equation

Table 3 reports the results for the quantity equation regression. The γ_i^r parameters, panel B, account for lagged signed trade quantity. The γ_1^Q parameters in the first column of results are positive and statistically significant for all countries for all periods. This indicates that a buy (sell) trade was likely to be followed by a buy (sell) trade. The lagged values of γ_i^Q in the second column of data are similarly positive and significant in all instances except for γ_2^Q Ireland in the pre-crisis calm period. Order splitting to minimise price impact is one potential reason for the finding that trades are likely followed by trades in the same direction. This is consistent with the discussion of the τ_0^r parameter results in the previous section. Executing large orders has a larger impact on price; market participants can minimise this impact by splitting large orders into smaller orders and dripping them into the market in the hope of preserving privileged information. Another potential reason is that when private events happen the privileged information becomes available to multiple market participants and they act on it within a short time frame until the opportunity no longer exists.

INSERT TABLES 3 AND 4 ABOUT HERE

The δ_i^r parameters account for market sector. This effect was strongest on MTS Domestic Markets for Germany where the δ_1^Q parameters are negative and significant across all periods. This implies that lagged trades on EuroMTS had a smaller instantaneous impact on current trades relative to the same

trade on MTS Domestic Markets. During the calm period, the δ_1^Q parameters are negative for France and Portugal, but only statistically significant for Portugal. It is positive for the remaining four countries. During the global financial crisis, the δ_1^Q parameters are negative for Greece, Ireland and Portugal, positive for Italy, France and Spain. All are statistically significant. During the European sovereign debt crisis, the δ_1^Q parameters are positive and significant for all countries other than Germany. This implies that lagged trades on EuroMTS had a larger instantaneous impact on current trades relative to the same trade on MTS Domestic Markets. There is no consistent pattern across the additional lagged variables, implying there was not one market segment that increased this effect. The τ_1^r parameters account for trading intensity. The τ_1^r parameters, panel C first column of results, are negative for all countries for all periods except Germany during the global financial crisis and Portugal during the European sovereign debt crisis. Taken in context with the generally positive δ_1^Q parameters, the likelihood that a trade was followed by a trade of the same direction decreased as the time between the trades increased. Again, this is consistent with the ideas of order splitting and multiple informed traders acting on the same private information. Table 4 reports the impact of a 5 million euro trade on the quoted price for the long benchmark instruments of the seven representative eurozone countries.

5. Conclusion

This paper uses high-frequency quote and transaction data from the MTS European sovereign bond inter-dealer platform to investigate the price-order-flow dynamics from July 2005 to December 2011 for Germany, France, Portugal, Italy, Ireland and Spain, Greece. We find that order-flow had a larger impact on quote revision in a relatively low-intensity trading environment than in a relatively high intensity trading environment implying that informed traders should only execute in low-intensity trading environments when they value immediacy over discretion. Further, we find that order-flows were strongly correlated, and the impact of order-flow on subsequent trades was larger during periods of high trading intensity. Taken together with the first main result, we conclude that market participants on the MTS market use order splitting as part of their trading strategy to minimise price impact, and that there are multiple informed traders acting on the same private information. To our knowledge Cheung et al. (2005) is the only other paper to provide a comparable analysis for the European sovereign bond market. Their dataset encompasses Italian, French, German and Belgian government bonds traded on MTS from January 2001 until May 2002. They report that the impact of a trade in a relatively low trading intensity environment has a larger impact on price than in a relatively high intensity environment. Our analysis shows that this result holds during the global financial crisis and European sovereign debt crisis.

There is significant scope to extend this analysis to inform policy. European capital markets were subject to updated Markets in Financial Instruments Regulation (MiFIR) and the accompanying Markets in

Financial Instruments Directive (MiFID II) from 3rd January 2018 that regulates both investment firms and trading venues. An obvious important extension of this paper would be to repeat our analysis to make use of quasi-experimental research design to assess the impact of these regulatory innovations.

Table 1. European sovereign benchmark bonds

Country (market)	Type	Ticker	Maturity	Number of bonds	Avg duration (yrs)	Avg coupon (%)	Avg daily quote vol (million)	Avg daily number of trades
France	BTA	BTNS	Short	8	2.4	2.4	203	1.4
(FRF)	BTA	BTNS	Medium	23	5.4	3.4	186	1.2
	OAT	FRTR	Long	30	10.6	4.7	363	2.6
Germany	DEM	BKO	Short	28	2.0	2.2	133	0.5
(GEM)	DEM	OBL	Medium	26	5.6	3.25	134	0.4
	DEM	DBR	Long	39	10.1	4.25	290	2.0
Italy	BTP	BTPS	Short	22	3.0	3.2	221	14.6
(MTS)	BTP	BTPS	Medium	21	5.1	3.8	208	13.9
	BTP	BTPS	Long	29	10.3	5.3	360	29.6
Greece	GGB	GGB	Short	6	3.3	3.1	95	1.1
(GGB)	GGB	GGB	Medium	9	5.3	4.3	118	1.2
	GGB	GGB	Long	16	9.9	5.6	190	4.4
Ireland	IRL	IRISH	Short	2	3.0	4.0	81	0.4
(IRL)	IRL	IRISH	Medium	3	5.6	3.8	63	0.5
	IRL	IRISH	Long	5	10.9	5.0	149	0.7
Portugal	PTE	PGB	Short	3	3.3	3.0	139	2.9
(PTE)	PTE	PGB	Medium	6	5.1	4.4	139	2.0
	PTE	PGB	Long	14	10.3	5.1	263	3.6
Spain	BON	SPGB	Short	6	3.1	3.0	170	1.6
(ESP)	BON	SPGB	Medium	12	5.1	3.7	168	1.9
	OBE	SPGB	Long	20	10.3	5.3	302	4.4

Notes: This table contains reference information for the benchmark instruments of the seven countries included in the analysis. The first column details the country and the MTS Domestic Markets identifier. The second and third columns detail two important MTS market identifiers: the bond type and ticker, respectively. The maturity column details whether the bond type is short-, medium- or long-term, defined as 1 to 3.5 years, 3.5 to 6.5 years and 6.5 to 13.5 years respectively. Descriptive statistics include the number of bonds per category, the average duration in years, the average coupon in percentage of par, the average daily quote volume in millions of euro, and the average daily number of trades.

Table 2. Returns equation

Notes: The table displays coefficients and T-statistics for the returns equation. T-statistics are shown in parentheses below the coefficient values. The dependent variable $r_t = 10,000 \ln(P_t/P_{t-1})$ is the change in the natural logarithm of the quoted prices; T_t is the time interval between two consecutive trades in seconds; Q_t is the signed trade quantity in millions; D_t is a dummy variable for the market indicator where 1 indicates a trade on the EuroMTS platform. Equation: $r_t = \bar{\alpha}^r + \sum_{i=1}^P (\bar{\beta}_i^r + \bar{z}_i^r \ln(T_{t-i})) r_{t-i} + \sum_{i=0}^P (\bar{\gamma}_i^r + \bar{\delta}_i^r D_{t-i} + \bar{\tau}_i^r \ln(T_{t-i})) Q_{t-i} + \varepsilon_{1,t}$, lags are truncated at $p=3$ in the estimation.

	p-value		0.215	<0.001

Notes: In Panel A the graphs display monthly number of transactions and average transaction size for the long benchmark instruments. Light blue indicates the transactions on the MTS Domestic Markets segment, dark blue the EuroMTS segment. Panel B displays the means for each of the three periods, and the mean differences between the first and second, and second and third periods. The panel displays coefficients, *t*-statistics and *P*-values; bold indicates significant at the 5% level.

Table 3. Quantities equation

Panel A: Quantities equation: returns, and intensity and returns

Notes: The table displays coefficients and T-statistics for the quantities equation. T-statistics are shown in parentheses below the coefficient values. The dependent variable $r_t = 10,000 \ln(P_t/P_{t-1})$ is the change in the natural logarithm of the quoted prices; T_t is the time interval between two consecutive trades in seconds; Q_t is the signed trade quantity in millions; D_t is a dummy variable for the market indicator where 1 indicates a trade on the EuroMTS platform. Equation: $Q_t = \bar{\alpha}^Q + \sum_{i=1}^P (\bar{\beta}_i^Q + \bar{z}_i^Q \ln(T_{t-i})) r_{t-i} + \sum_{i=1}^P (\bar{y}_i^Q + \bar{\delta}_i^Q D_{t-i} + \bar{\tau}_i^Q \ln(T_{t-i})) Q_{t-i} + \varepsilon_{2,t}$, lags are truncated at $p=3$ in the estimation.

Table 4. Impact of a trade on the quoted price

		MTS Domestic	EuroMTS
		Markets	
Germany	Calm	0.197	0.206
	Glob fin. crisis	0.143	-0.028
	Euro sov. debt crisis	0.114	0.127
